Sensor networks aim at monitoring their surroundings for event detection and object tracking. But, due to failure, or death of sensors, false signal can be transmitted. In this paper, we consider the problems of distributed fault detection in wireless sensor network (WSN). In particular, we consider how to take decision regarding fault detection in a noisy environment as a result of false detection or false response of event by some sensors, where the sensors are placed at the center of regular hexagons and the event can occur at only one hexagon. We propose fault detection schemes that explicitly introduce the error probabilities into the optimal event detection process. We introduce two types of detection probabilities, one for the center node, where the event occurs and the other one for the adjacent nodes. This second type of detection probability is new in sensor network literature. We develop schemes under the model selection procedure, multiple model selection procedure and use the concept of Bayesian model averaging to identify a set of likely fault sensors and obtain an average predictive error.

Keywords: Event Detection, Wireless Sensor Network, Multiple Model Selection, Bayesian Model Averaging.

1. Introduction

Traditional and existing *sensor-actuator networks* use wired communication, whereas wireless sensor networks (WSN) provide radically new communication and networking paradigms and myriad new applications. The wireless sensors have small size, low battery capacity, non-renewable power supply, small processing power, limited buffer capacity and low-power radio. They may measure distance, direction, speed, humidity, wind speed, soil makeup, temperature, chemicals, light, and various other parameters.

Recent advancements in wireless communications and electronics have enabled the development of low-cost WSN. A WSN usually consists of a large number of small sensor nodes, which are equipped with one or more sensors, some processing circuit, and a wireless transceiver. One of the unique features of a WSN is random deployment in inaccessible terrains and cooperative effort that offers unprecedented opportunities for a broad spectrum of civilian and military applications, such as industrial automation, military surveillance, national security, and emergency health care [1, 2, 20]. Sensor Networks are also useful in detecting topological events such as forest fires [10].

Sensor networks aim at monitoring their surroundings for event detection and object tracking [2, 17]. Because of this surveillance goal, *coverage* is the functional basis of any sensor network. In order to fulfill its designated tasks, a sensor network must fully cover the Region of Interest (ROI) without leaving any *internal sensing hole* [3, 5, 6, 9]. So far, a number of movement-assisted sensor placement algorithms have been proposed. An exclusive survey on these topics is presented by Li et al. [14]. On the other hand sensor could die or fail at runtime for various reasons such as power depletion, hardware defects, etc. So, even after the ROI is fully covered by the sensors, wrong information can be communicated by some sensors, or sensors may fail to detect the event due to noise or obstructions. Chen et al. [8] have proposed a distributed localized fault detection algorithm for WSN, where each sensor identifies its own status to be either good or faulty and the claim is then supported or reverted by its neighbors. The proposed algorithm is analyzed using a probabilistic approach. Sharma et al. [21] have characterized the different types of fault and proposed a different algorithm for fault detection considering different types of fault. Some of the methods are statistical, like, using histogram, etc. Both the work can only detect the faulty sensors, but not the event.

One of the important sensor network applications is monitoring inaccessible environments. Sensor networks are used to determine event regions and boundaries in the environment with a distinguishable characteristic [7, 13, 19]. The basic idea of distributed detection [22] is to have each of the independent sensors make a local decision (typically, a binary one, i.e., an event occurs or not) and then combine these decisions at a fusion sensor (the sensor which collects the local information and takes the decision), or at a base station to generate a global decision.

1.1 Our Motivation

In this paper, we are interested in one particular query: determining event in the environment (i.e., ROI) with a distinguishable characteristic. We assume the ROI to be partitioned into suitable number of congruent regular hexagonal cells (i.e., we can think ROI as a regular hexagonal grid). This physical structure of ROI is not a requirement for the theoretical analysis, we can do the similar analysis with other structure also. Suppose that sensors are placed a priori at the center (which are known as nodes) of every hexagon of the grid. We assume that the sensors are connected to its adjacent sensor nodes in the sense that a hexagon will be strongly covered by its center node and weakly covered by the adjacent nodes. If event occurs in the hexagon where a particular sensor lies, then that particular sensor can detect the event with a greater probability whereas, if event occurs in any adjacent hexagon, then the particular sensor can detect the event with a lesser probability. Hence, only one node (center node of the event hexagon) can detect the event hexagon with greater probability, say p_1 , and adjacent nodes (six for interior nodes and less for boundary nodes) can detect the event hexagon with lesser probability, say p_2 , with $p_1 > p_2$. We assume that no other sensor can detect the event hexagon. In this paper, unlike the previous works, we assume that if the event occurs then it occurs at only one hexagon of the grid which will be known as event hexagon and there is no fusion sensor. All sensors can communicate with the base station and the base station takes the decision about the query. As an example, consider a network of devices that are capable of sensing mines or bombs, if we assume that a few mines or bombs may be placed on a particular area of ROI. Information from these devices can be sent to a nearby police station, or a central facility. Then, an important query in this situation could be whether a particular hexagon is the event hexagon or not (i.e., mines or bombs are placed or not).

One fundamental challenge in the event detection problem for a sensor network is the detection accuracy which is disturbed by the noise associated with the detection and the reliability of sensor nodes. A sensor may fail to detect the event due to natural obstruction or any other causes. After detecting the event, a sensor can send false message to the base station due to some technical reasons. The sensors are usually low-end inexpensive devices and sometimes exhibit unreliable behavior. For example, a faulty sensor node may issue an alarm even though it has not received any signal for event, or it cannot detect any event, and vice versa. Moreover, a sensor may be dead, in which case, the sensor cannot send any alarm.

1.2 Our Contribution

In our theoretical analysis, the sensor fault probabilities are introduced into the optimal event detection process. We apply model selection approach, multiple model selection approach and Bayesian model averaging methods [12, 18] to find a solution of the problem. We develop the schemes using the model selection technique. We calculate different error probabilities and find some theoretical results.

In all previous works, the authors assume only one detection probability. We introduce two detection probabilities, p_1 and p_2 , one for the center node and other for the adjacent nodes. Even if the center node may fail to detect the event, the adjacent nodes may detect the event, and vice versa. We consider these probabilities and show that, in various situations, the adjacent nodes play key role to detect the event. One can introduce more detection probabilities and analyze the situation in similar manner.

The parameters p_1 and p_2 , the detection probabilities of a sensor, and error probabilities (see Section 4) cannot be estimated from the real life situations, but need to be estimated beforehand by some experimentation. The prior probabilities of various events also cannot be estimated, but may be known in some cases. Finally, we calculate the error probabilities numerically for some values of the parameters of our model and make some concluding remarks analyzing the results.

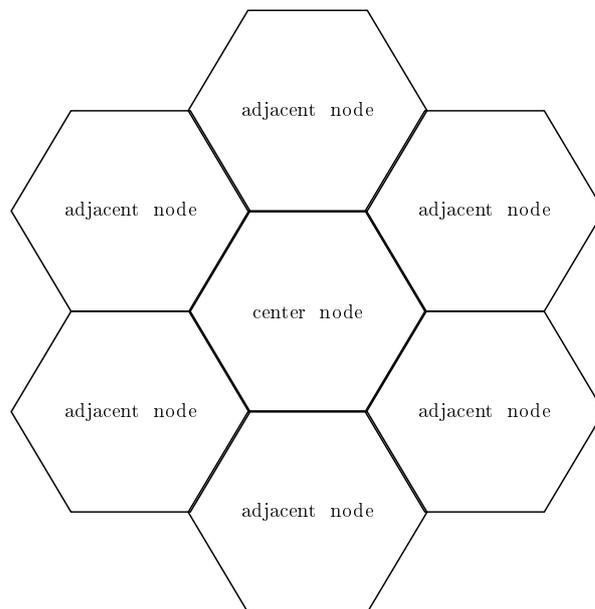

2. Previous Work

Lou et al. [15] consider two important problems for distributed fault detection in WSN: 1) how to address both the noise-related measurement error and sensor fault simultaneously in fault detection and 2) how to choose a proper neighborhood size n for a sensor node in fault correction such that the energy could be conserved. They propose a fault detection scheme that explicitly introduces the sensor fault probability into the optimal event detection process. They show that the optimal detection error decreases exponentially with the increase of the neighborhood size.

Krishnamachari and Iyengar [13] propose a distributed solution for canonical task in WSN (i.e., the binary detection of interesting environmental events). They explicitly take into account the possibility of sensor measurement faults and develop a distributed Bayesian algorithm for detecting and correcting such faults.

Nandi et al. [16] consider the problem of distributed fault detection in wireless sensor network (WSN), where the sensors are placed at the center of a particular square (or hexagon) of the grid covering the ROI. They proposed fault detection schemes that explicitly introduce the error probabilities into the optimal event detection process. They developed the schemes under the consideration of Neyman-Pearson hypothesis test and Bayes test. They also calculate type I and type II errors for different values of the parameters.

Figure 1.: Nodes placed in centers when ROI partitioned in to regular hexagons

In almost all the previous works, except [16], authors assume that event occurs over a region and there are fusion sensors that collect the information locally and take a decision. Since they do not introduce the concept of base station there is no concept of response probability. Also, they assume informations are spatially correlated. Unlike the previous work, in this paper, we assume that if event occurs then it occurs at only one cell of the ROI and there is no fusion sensor. All the sensors send information to the base station. We introduce the probability model in two different stages; firstly, when a sensor detects the event and, secondly, when a sensor sends the message to the base station. In the previous works, only one type of detection probability has been introduced to simulate the different error probabilities for some specific values of the parameters. In this paper, we introduce two different detection probabilities and obtain analytically the exact test and estimate the error probabilities by simulation. In almost all the previous works, authors assume the ROI to be a square grid. The hexagonal grid is better in the sense that minimum number of sensors are required to cover the entire ROI [23].

3. Statement of the problem and Assumptions

In this section, we describe the problem in more specific terms and state the assumptions that we make.

Sensors are deployed, or manually placed, over ROI to perform event detection (i.e., to detect whether an event of interest has happened or not) in ROI. If sensors are deployed from air then, using actuator-assisted sensor placement or by movement-assisted sensor placement, sensors are so placed that sensor network covers the entire ROI. This ROI is partitioned into suitable number of regular hexagons (i.e., we can think of the ROI as a regular hexagonal grid), as shown in Figure 1. Sensors are placed a priori at every center (which are known as nodes) of the regular hexagons. Sensors have two detection probabilities. The sensor network covers the entire ROI and there is only one event hexagon, as discussed before.

Each sensor node determines its location through beacon positioning mechanisms [4] or by exploiting the Global Positioning System (GPS). Through a broadcast

or acknowledge protocol, each sensor node is also able to locate the neighbors within its communication radius. Sensors are also able to communicate with the base station. Base station will take the decision. In this paper, we assume that, event occurs at one particular hexagon of the grid which will be known as *event hexagon* or event does not occur (in that case we say ROI is *normal*). All sensors can communicate with the base station and base station takes the decision by combining the information received from all the sensors.

There are two phases in the whole process. The first one is detection phase, when the sensor at the center of a regular hexagon tries to detect the event. The sensor at the center of the event hexagon can detect the event hexagon with greater probability p_1 and the sensors at the adjacent nodes (see Figure 1) can detect the event hexagon with lesser probability p_2 . We also assume that there is a prior probability that a particular hexagon is an event hexagon. The next phase is response phase, in which sensors send message to the base station. Even if the event hexagon is detected by a sensor, it may not respond (i.e., send message to the base station that no event occurred in that cell and the neighboring cells due to some technical fault) with some probability; then we say that the sensor is a *faulty sensor*. Conversely, if event hexagon is not detected, or there is no event hexagon at all (i.e., ROI is normal), then also a faulty sensor can send the wrong information to the base station with some probability. A sensor is said to be a *dead sensor* if the sensor does not work. A dead sensor sends no response in either cases.

Each sensor sends information to the base station. As the sensors may send wrong information, the base station takes the important role in identifying the event hexagon. Base station will collect all the information and take a decision about the event hexagon according to a rule which we have to find out. Our job is to find a rule for the base station such that base station works most efficiently.

3.1 Notations and Assumption

Our problem is to develop a strategy for the base station to take decision about event hexagon (i.e., which hexagon of the ROI is the event hexagon, if at all). Let R be the set of all nodes. For $N \in R$, define $B(N)$, as the set of adjacent node(s) of N and $k(N)$ be the number of adjacent node(s) of N . Hence, $0 \leq k(N) \leq 6$. Call a node N interior if $k(N) = 6$. Let S_N be the sensor which is placed at the node N and H_N be the hexagon where the node N is placed (i.e., N is the center of H_N). For $N \in R$, let X_N denote the true status of the node N . That is, $X_N = 1$ if event occurs at H_N , and 0 otherwise. Also define $Y_N = 0$ if S_N detects no event, and 1 if S_N detects the event in H_N or $H_{N'}$, for $N' \in B(N)$. Finally define $Z_N = 0$ if S_N does not respond, i.e., the sensor informs the base station that event does not occur at H_N or $H_{N'}$ for $N' \in B(N)$, and $Z_N = 1$ if S_N responds, i.e., the sensor S_N informs the base station that the event has occurred in H_N or $H_{N'}$, for $N' \in B(N)$.

Now we make one natural assumption that, once detection phase is completed, response of a sensor depends only on what it detects but not on whether the event has actually occurred or not, i.e., $P(Z_N = k|Y_N, X_N) = P(Z_N = k|Y_N)$, for $k = 0, 1$. We also assume that the sensors work independently and identically.

Since we assume that there is at most one event hexagon, $\sum_{N \in R} X_N = 1$ or 0. The possible true scenarios are, therefore, represented by the following $|R| + 1$ different models:

- $\mathcal{M}_0 : (X_N = 0 \text{ for all } N \in R),$
- and, for each $N \in R,$
- $\mathcal{M}_N : (X_N = 1 \text{ and } X_{N'} = 0 \text{ for all } N' \in R \setminus N).$
- Let $\Pr(\mathcal{M}_0) = P(\text{ROI is normal}) = p_{norm}$

and, for all $N \in R$, $\Pr(\mathcal{M}_N) = \Pr(\text{event occurs at the hexagon } H_N) = p_N$.

In particular, we may assume p_N 's to be same for all N . We denote any probability under the model \mathcal{M}_0 as $P_{\mathcal{M}_0}(\cdot)$ and under the model \mathcal{M}_N as $P_{\mathcal{M}_N}(\cdot)$.

We also make the followings assumptions:

- For all $N \in R$, $P_{\mathcal{M}_0}(Y_N = 1) = 0$ and $P_{\mathcal{M}_N}(Y_N = 1) = p_1$.
- For all $N' \in B(N)$, $P_{\mathcal{M}_N}(Y_{N'} = 1) = p_2$, and for all $N' \in R \setminus [B(N) \cup \{N\}]$, $P_{\mathcal{M}_N}(Y_{N'} = 1) = 0$.
- For all $N \in R$, $P(Z_N = 1|Y_N = 1) = p_c$ and $P(Z_N = 1|Y_N = 0) = p_w$.
- Z_N and $Y_{N'}$ are independent for $N \neq N'$.
- The responses from different nodes are independent under a particular model, i.e., Z_N 's are independent under $\mathcal{M}_{N'}$ for a fixed $N' \in R$.

4. Theoretical Analysis of fault Detection

In this section we discuss some theoretical results. In real situations, $|R|$ may be very large. Given the network of the sensor nodes and some prior knowledge about the nature of event, one may have fairly good idea about the set of feasible regions for the event. Formally, instead of all possible models, one may be able to restrict to a set containing all the feasible models. For example, if the event is known to take place in a particular region, we can restrict our models accordingly.

4.1 Model Selection Approach

$$\begin{aligned} \text{For all } N \in R, P_{\mathcal{M}_0}(Z_N = 1) \\ &= P_{\mathcal{M}_0}(Z_N = 1|Y_N = 0)P_{\mathcal{M}_0}(Y_N = 0) + P_{\mathcal{M}_0}(Z_N = 1|Y_N = 1)P_{\mathcal{M}_0}(Y_N = 1) \\ &= P(Z_N = 1|Y_N = 0)P_{\mathcal{M}_0}(Y_N = 0) + P(Z_N = 1|Y_N = 1)P_{\mathcal{M}_0}(Y_N = 1) = p_w. \end{aligned}$$

Hence, under the model \mathcal{M}_0 , Z_N follows $\text{Ber}(p_w)$, for all $N \in R$, and the likelihood of the data $\{Z_N = z_N, \text{ for all } N \in R\}$, under the model \mathcal{M}_0 , is

$$\begin{aligned} L_0 &= P_{\mathcal{M}_0}(Z_N = z_N, \text{ for all } N \in R) \\ &= \prod_{N \in R} p_w^{z_N} (1 - p_w)^{(1-z_N)} = (p_w)^{\sum_{N \in R} z_N} \times (1 - p_w)^{\sum_{N \in R} (1-z_N)}. \end{aligned}$$

So $\ln L_0 = \sum_{N \in R} z_N \ln p_w + \sum_{N \in R} (1 - z_N) \ln(1 - p_w)$.

$$\begin{aligned} \text{For any } N \in R, \text{ we have } P_{\mathcal{M}_N}(Z_N = 1) \\ &= P_{\mathcal{M}_N}(Z_N = 1|Y_N = 0)P_{\mathcal{M}_N}(Y_N = 0) + P_{\mathcal{M}_N}(Z_N = 1|Y_N = 1)P_{\mathcal{M}_N}(Y_N = 1) \\ &= P(Z_N = 1|Y_N = 0)P_{\mathcal{M}_N}(Y_N = 0) + P(Z_N = 1|Y_N = 1)P_{\mathcal{M}_N}(Y_N = 1) \\ &= p_w(1 - p_1) + p_c p_1 = p_1(p_c - p_w) + p_w = P_1, \text{ say.} \end{aligned}$$

Hence, for all $N \in R$, under \mathcal{M}_N , Z_N follows $\text{Ber}(P_1)$. Similarly, for all $N' \in B(N)$, under \mathcal{M}_N , $Z_{N'}$ follows $\text{Ber}(P_2)$, where $P_2 = p_2(p_c - p_w) + p_w$ and, under \mathcal{M}_N , $Z_{N'}$ follows $\text{Ber}(p_w)$ for all $N' \in R \setminus [B(N) \cup \{N\}]$. Note that $P_1 > P_2$ since $p_1 > p_2$. Hence the likelihood for the model \mathcal{M}_N , given $Z_{N'} = z_{N'}, N' \in R$, is

$$L_N = P_{\mathcal{M}_N}(Z_{N'} = z_{N'}, \text{ for all } N' \in R) =$$

$$\begin{aligned}
 & P_1^{z_N} (1 - P_1)^{(1-z_N)} \prod_{N' \in B(N)} P_2^{z_{N'}} (1 - P_2)^{(1-z_{N'})} \\
 & \times \prod_{N' \in R \setminus [B(N) \cup \{N\}]} p_w^{z_{N'}} (1 - p_w)^{(1-z_{N'})} \\
 & = P_1^{z_N} (1 - P_1)^{(1-z_N)} P_2^{\sum_{N' \in B(N)} z_{N'}} (1 - P_2)^{\sum_{N' \in B(N)} (1-z_{N'})} \\
 & \times p_w^{\sum_{N' \in R \setminus [B(N) \cup \{N\}]} z_{N'}} (1 - p_w)^{\sum_{N' \in R \setminus [B(N) \cup \{N\}]} (1-z_{N'})}.
 \end{aligned}$$

Let $T_N = \sum_{N' \in B(N)} Z_{N'}$, so that $\sum_{N' \in B(N)} (1 - Z_{N'}) = k(N) - T_N$

with the corresponding observed values denoted by

$$t_N = \sum_{N' \in B(N)} z_{N'} \text{ and } \sum_{N' \in B(N)} (1 - z_{N'}) = k(N) - t_N.$$

Therefore, $\ln L_N =$

$$\begin{aligned}
 & z_N \ln P_1 + (1 - z_N) \ln(1 - P_1) + t_N \ln P_2 + (k(N) - t_N) \ln(1 - P_2) \\
 & + \sum_{N' \in R \setminus [B(N) \cup \{N\}]} z_{N'} \ln p_w + \sum_{N' \in R \setminus [B(N) \cup \{N\}]} (1 - z_{N'}) \ln(p_w(1 - p_w)) \\
 & = \ln L_0 + z_N \ln \frac{P_1}{p_w} + (1 - z_N) \ln \frac{1 - P_1}{1 - p_w} + t_N \ln \frac{P_2}{p_w} + (k(N) - t_N) \ln \frac{1 - P_2}{1 - p_w} \\
 & = \ln L_0 + z_N \ln \frac{P_1(1 - p_w)}{p_w(1 - P_1)} + t_N \ln \frac{P_2(1 - p_w)}{p_w(1 - P_2)} + \ln \frac{1 - P_1}{1 - p_w} + k(N) \ln \frac{1 - P_2}{1 - p_w} \\
 & = a + b(cz_N + t_N - dk(N)), \text{ say,}
 \end{aligned}$$

where, $a = \ln L_0 + \ln \frac{1 - P_1}{1 - p_w}$, $b = \ln \frac{P_2(1 - p_w)}{p_w(1 - P_2)} > 0$,

$$c = \frac{\ln \frac{P_1(1 - p_w)}{p_w(1 - P_1)}}{\ln \frac{P_2(1 - p_w)}{p_w(1 - P_2)}} \text{ and } d = \frac{\ln \frac{1 - p_w}{1 - P_2}}{\ln \frac{P_2(1 - p_w)}{p_w(1 - P_2)}} \text{ are independent of } N.$$

In model selection approach, the model resulting in the maximum value of the likelihood is selected. Note that, since there is no parameter being estimated, this is equivalent to the well-known Akaike Information Criterion(AIC) [11]. Therefore, the base station will accept the model \mathcal{M}_0 if

$$= \ln \frac{1 - P_1}{1 - p_w} + b(cz_N + t_N - dk(N)) < 0, \text{ for all } N \in R.$$

Otherwise, as b is positive, accept the model \mathcal{M}_N for which $(cz_N + t_N - dk(N))$ is maximum among all $N \in R$. If values of $(cz_N + t_N - dk(N))$ are equal for more than one N , then we can select one of the corresponding models with equal probability. If we want to maximize the likelihood for the models \mathcal{M}_N corresponding to the interior nodes only, so that $k(N)$ is fixed, then we need to maximize $(cz_N + t_N)$ among all $N \in R$.

4.2 Multiple Model Selection

Instead of selecting one particular model, one may want to select more than one models with approximately similar log likelihood values to the maximum one. We

can consider the set of models

$$\{\mathcal{M}_K : \frac{L_K}{\max_{N \in R} L_N} > C\},$$

where $0 < C < 1$ is a suitable constant close to 1. This C is usually chosen according to the resource available. This is similar to the idea of Occam's window in the context of Bayesian model selection [12]. This may be interpreted as the interval estimation for the true model.

Note that L_N is an increasing function of $cz_N + t_N - dk(N)$, as b is positive. We consider only the following set of models

$$\{\mathcal{M}_K : Q_K > C^* \cdot \max_{N \in R} Q_N\},$$

where $Q_N = cz_N + t_N - dk(N)$, for all $N \in R$, with $0 < C^* < 1$. In particular, if we consider the interior nodes only, then we consider the set of models given by

$$\{\mathcal{M}_K : cz_K + t_K > C^* \cdot \max_{N \in R} \{cz_N + t_N\}\}.$$

We can select multiple models using some other criteria. One such may be to select all the models (one or more) for which the maximum value of the likelihood is attained. Let \mathcal{N}_{\max} be the set of nodes corresponding to all these models, including ' $N = 0$ ' corresponding to \mathcal{M}_0 if it has the maximum value of the likelihood. Then this method select all the models \mathcal{M}_N with $N \in \mathcal{N}_{\max}$. By another criterion, one may select the models $\mathcal{M}_{N'}$, for $N' \in \mathcal{N}_{\max} \cup [\cup_{N \in \mathcal{N}_{\max}} B(N)]$; that is, N' be a node in \mathcal{N}_{\max} or any of the neighboring nodes of a node in \mathcal{N}_{\max} . Note that $B(N)$ for $N = 0$ is the empty set. One can combine these two types of criteria and come up with many others.

4.3 Bayesian Model Averaging

Bayesian model averaging is an effective method to solve a decision problem when there are many alternative hypotheses or models, which are complicated [12]. Suppose $\mathcal{M}_1, \mathcal{M}_2, \dots, \mathcal{M}_k$ are the models considered and D denotes the given data. The posterior probability for model \mathcal{M}_k is given by

$$\Pr(\mathcal{M}_k | D) = \frac{\Pr(D | \mathcal{M}_k) \Pr(\mathcal{M}_k)}{\sum \Pr(D | \mathcal{M}_l) \Pr(\mathcal{M}_l)},$$

where $\Pr(D | \mathcal{M}_k)$ denotes the probability of observing data D under the model \mathcal{M}_k (which is essentially the likelihood L_k under \mathcal{M}_k) and $\Pr(\mathcal{M}_k)$ is the prior probability that \mathcal{M}_k is the true model (assuming that one of the models is true).

In this work, the data D is $\{Z_N = z_N : N \in R\}$ and the models are $\mathcal{M}_0, \mathcal{M}_N, N \in R$ as defined in Section 3.2. Hence, The posterior probability for model \mathcal{M}_N is

$$\Pr(\mathcal{M}_N | Z_N = z_N, N \in R) = \frac{p_N L_N}{\sum_{l \in R} p_l L_l + p_{norm} L_0},$$

and that for \mathcal{M}_0 is $\frac{p_{norm} L_0}{\sum_{l \in R} p_l L_l + p_{norm} L_0}$.

We select the model \mathcal{M}_0 if $p_{norm}L_0$ is greater than $p_N L_N$, for all $N \in R$; otherwise, select \mathcal{M}_N for which $p_N L_N$ is maximum among all $N \in R$. Hence, if p_N 's are all equal, then Bayesian approach is same as the likelihood approach.

5. Some Important Considerations and Error Probabilities

In this section, we consider some important issues related to the problem of fault detection and the proposed methodology including calculation of errors (e.g., false detection, etc.) and detection probabilities.

The following probabilities give some idea about the role of neighboring nodes, along with the center node, in detection, or false detection, of event. For example, $P_{\mathcal{M}_0}(T_N = 0, Z_N = 1)$ gives the probability of a false detection by the N^{th} node, and not by the neighboring nodes, while $P_{\mathcal{M}_N}(T_N = 6, Z_N = 0)$ gives the probability of a false negative by the N^{th} node, with all the neighboring nodes detecting the event. Since, given a particular model, T_N and Z_N are independent, calculation of such probabilities is simple as given in the following. For any $N \in R$ and $i = 0, 1, \dots, k(N)$,

- (1) $P_{\mathcal{M}_0}(T_N = i, Z_N = 0) = \binom{k(N)}{i} p_w^i (1 - p_w)^{k(N)-i+1}$
- (2) $P_{\mathcal{M}_0}(T_N = i, Z_N = 1) = \binom{k(N)}{i} p_w^{i+1} (1 - p_w)^{k(N)-i}$
- (3) $P_{\mathcal{M}_N}(T_N = i, Z_N = 0) = \binom{k(N)}{i} P_2^i (1 - P_2)^{k(N)-i} (1 - P_1)$
- (4) $P_{\mathcal{M}_N}(T_N = i, Z_N = 1) = \binom{k(N)}{i} P_2^i (1 - P_2)^{k(N)-i} P_1.$

Note that, for $N \in R$, $P_{\mathcal{M}_0}(L_N > L_0) = P_{\mathcal{M}_0}(\ln L_N > \ln L_0) =$

$$P_{\mathcal{M}_0} \left(Z_N \ln \frac{P_1(1-p_w)}{p_w(1-P_1)} + T_N \ln \frac{P_2(1-p_w)}{p_w(1-P_2)} + \ln \frac{1-P_1}{1-p_w} + k(N) \ln \frac{1-P_2}{1-p_w} > 0 \right)$$

$$= P_{\mathcal{M}_0} \left(Z_N \ln \frac{P_1(1-p_w)}{p_w(1-P_1)} + T_N \ln \frac{P_2(1-p_w)}{p_w(1-P_2)} > k(N) \ln \frac{1-p_w}{1-P_2} + \ln \frac{1-p_w}{1-P_1} \right),$$

which can be numerically obtained using the joint distribution of T_N and Z_N under the model \mathcal{M}_0 . The maximum of these probabilities over all N gives a lower bound for the probability that a node is considered to be an event node when the ROI is normal. On the other hand, the sum over all N gives an upper bound for the same. Similarly, for $N \in R$, $P_{\mathcal{M}_N}(L_N < L_0) =$

$$P_{\mathcal{M}_N} \left(Z_N \ln \frac{P_1(1-p_w)}{p_w(1-P_1)} + T_N \ln \frac{P_2(1-p_w)}{p_w(1-P_2)} < k(N) \ln \frac{1-p_w}{1-P_2} + \ln \frac{1-p_w}{1-P_1} \right),$$

which can be again numerically obtained using the joint distribution of T_N and Z_N under the model \mathcal{M}_N . This probability gives some idea about the error that, when N^{th} node is the event node and it is not detected.

As noted in Section 4.1, we select the model \mathcal{M}_N for which Q_N is the maximum, for $N \in R$. The random variable Q_N is, therefore, of some interest, the distribution of which under different models is useful in calculating many error probabilities. We first find the distribution of Q_N under the model \mathcal{M}_N . Note that Q_N takes values $ci + j - dk(N)$, corresponding to $Z_N = i$ and $T_N = j$, for $i = 0, 1$, and $j = 0, 1, 2, \dots, k(N)$. Assume that, for convenience, the values of Q_N for different i

and j are all distinct. Therefore, for $i = 0, 1$ and $j = 0, 1, \dots, k(N)$,

$$P_{\mathcal{M}_N}(Q_N = ci + j - dk(N)) = \binom{k(N)}{j} (P_1)^i (1 - P_1)^{(1-i)} (P_2)^j (1 - P_2)^{(k(N)-j)}$$

$$\text{and, } P_{\mathcal{M}_0}(Q_N = ci + j - dk(N)) = \binom{k(N)}{j} (p_w)^{i+j} (1 - p_w)^{(1-i+k(N)-j)}.$$

For $N' \in B(N)$, or $N' \in R \setminus [B(N) \cup \{N\}]$, one can find $P_{\mathcal{M}_{N'}}(Q_N = ci + j - dk(N))$ in similar manner, although the calculation is very tedious as there are many sub-cases. Ideally, one is interested in probability of errors occurring at the level of base station. For example, the two important errors are: (1) not selecting \mathcal{M}_0 when \mathcal{M}_0 is true (false positive), and (2) selecting \mathcal{M}_0 when \mathcal{M}_N is true for some $N \in R$ (false negative). Theoretical calculation of these error probabilities is complicated. We, therefore, use simulation technique to estimate these and similar error probabilities.

6. Simulation Study

We consider a 32×32 hexagonal grid and we run the programme 10000 times. The simulation is performed using the C-code, and required random numbers are generated using the standard C-library.

In our simulation study, we consider different criteria, as discussed in Sections 4.1 and 4.2, for estimating the error probabilities, or equivalently, the success rate. First consider the probability of selecting \mathcal{M}_0 , when it is true. Let S_1 denote the proportion of correct detection of normal situation, when model \mathcal{M}_0 is true, using the model selection method of Section 4.1. That is, S_1 gives an estimate of $P_{\mathcal{M}_0}(0 \in \mathcal{N}_{max}$ and 0 is selected by randomization). Then $1 - S_1$ gives an estimate of the false positive rate.

When \mathcal{M}_N is true for some $N \in R$, let S_2 denote the proportion of correct decision for the event node using the model selection method of Section 4.1, so that it estimates $P_{\mathcal{M}_N}(N \in \mathcal{N}_{max}$ and is selected by randomization). Note that, for each simulation run, the event hexagon is chosen randomly so that S_2 gives an average value over all N . In this context, this probability is same for all the interior nodes. Then, $1 - S_2$ gives an estimate of the corresponding error probability of not selecting \mathcal{M}_N , when it is true.

Note that, in this problem of fault detection with a single event node, the likelihood value, for a given observed data configuration, may be equal for more than one models. Therefore, quite often, the maximum value of the likelihood may be attained by more than one model. The model selection method of Section 4.1, which selects one of these models randomly in such cases, may often not select the correct model. Therefore, the method of Section 4.2, which selects more than one models having similar likelihood value, may be preferred and will have better chance of selecting the correct model. We now consider some of those methods in the following.

Let us first consider the method in which all the models corresponding to the maximum value of the likelihood are selected. Let S_3 denote the proportion of correct selection of the model \mathcal{M}_N , when it is true, by this method. Then S_3 estimates the probability $P_{\mathcal{M}_N}(N \in \mathcal{N}_{max})$, which is always more than or equal to the quantity estimated by S_2 , as remarked before. We also consider the method in which all the models having maximum likelihood along with their neighborhood models are selected. A model $\mathcal{M}_{N'}$ is a neighborhood model of the model \mathcal{M}_N if

N' is a neighboring node of N . If S_4 denotes the proportion of correct selection of the model \mathcal{M}_N , when it is true, by this method, then S_4 estimates $P_{\mathcal{M}_N}(N \in \mathcal{N}_{\max} \cup \{\cup_{N' \in \mathcal{N}_{\max}} B(N')\})$. Clearly, $S_4 \geq S_3 \geq S_2$. Similarly, if S_5 denotes the proportion of correct selection of the model \mathcal{M}_N , when it is true, by selecting all those models with likelihood value being more than 90% of the maximum likelihood (that is, the method of Section 4.2 with $C = 0.9$) then S_5 estimates the probability $P_{\mathcal{M}_N}(L_N > 0.9L_{max})$ with L_{max} denoting the maximum value of the likelihood.

Table 1.: Simulation of estimated probabilities for some values of the parameters

Suppose N_i denotes the average number of selected nodes to be searched corresponding to S_i , $i = 1, 2, \dots, 5$. Clearly, $N_1 = 1 - S_1$ because we need no search when \mathcal{M}_0 is selected. When event occurs and we consider only one N from \mathcal{N}_{\max} , we need at most one search (since no search is needed if \mathcal{M}_0 is selected) and we have $N_2 \leq 1$. In our simulation, we find $N_2 = 1$ in all the cases; that means, in simulation, \mathcal{M}_0 has not been selected when event occurred. Note that $N_3 \geq 1$ since we consider all N 's in \mathcal{N}_{\max} for searching. Again, as before, $N_4 > N_3 \geq 1 \geq N_2$. Also, by definition, $N_5 \geq 1$. Table 1 presents the different S_i 's and N_i 's based on simulation for different values of p_1, p_2, p_c and p_w with p_1 and p_c taking values 0.9 and 0.99, p_w taking values 0.01 and 0.001 and p_2 taking values 0.0, 0.3, 0.4, 0.5 and 0.6. The choice of p_1 and p_c reflects the corresponding high probability, whereas that of p_w reflects small probability, which is desirable in a good sensor. Since the primary interest is to study the effect of detection by neighboring nodes, we consider p_2 as 0 (which means there is no effect of neighboring nodes) and some positive values less than p_1 .

Note that the probability of correct detection under \mathcal{M}_0 depends only on p_w . This is also evident in Table 1. Intuitively, if p_w is high then the proportion S_1 of correct detection in normal situation is low. In Table 1, we see that S_1 is 0 for $p_w = 0.01$, varies from 0.35 to 0.37 for $p_w = 0.001$ and varies from 0.90 to 0.91 for $p_w = 0.0001$ (not shown in Table 1). If we consider smaller value of p_w then the success probability S_1 will be higher. Hence p_w must be low as the number of hexagons is high to get better results in normal situation.

We see that the estimated false negative rate, that is an estimate of $P_{\mathcal{M}_N}(\mathcal{M}_0 \text{ is selected})$, is often 0 in our simulation (not shown in Table 1). This is because, if the event occurs at N , then detection of the event by at least one of the nodes belonging to $\{N\} \cup B(N)$ is highly probable. Furthermore, since the grid size is large, one of the node belonging to $R \setminus (\{N\} \cup B(N))$ may response wrongly, though it cannot detect the event. So, under \mathcal{M}_N , there is a small probability to select ROI as normal. If we take p_w and the detection probabilities p_1 and p_2 to be very small, then we may get some positive false negative rate but this is not a desired condition for a good sensor.

From simulation, we see that, as p_2 increases (for positive p_2), S_i values increase whereas N_i decrease. As p_2 increases, it helps to differentiate between the likelihood values resulting in lower cardinality of the set \mathcal{N}_{\max} and lower values of N_i 's. However, since the neighboring nodes help to detect the event, the success probability increases. From simulation, we find that, as p_1 increases, success probabilities also increase, but the effect of p_2 is more prominent than that of p_1 . On the other hand, success probabilities also change with p_w and p_c . Since $p_2 = 0$ means $P_2 = p_w$, so there is little variability in the likelihood values leading to larger size of \mathcal{N}_{\max} .

When $p_w = 0.01$, effect of p_2 on S_3, S_4, S_5 and N_3, N_4, N_5 seems to be significant, whereas the same cannot be said for $p_w = 0.001$. There is sudden change in S_i 's and N_i 's, when we shift from $p_2 = 0$ to $p_2 = 0.3$, for $p_w = 0.01$, but not $p_w = 0.001$. So, when p_w is small, the effect of the neighborhood seems to be less.

The values of S_3 and S_4 are very similar for different values of the parameters; but large increment in N_4 than N_3 suggests that the idea of neighboring search is not effective. But S_3 is much higher than S_2 ; so the method of searching all the nodes in \mathcal{N}_{\max} is a better idea than that of searching a random node from \mathcal{N}_{\max} .

We estimate the success probability $P_{\mathcal{M}_N}(L_N > C.L_{max})$ by simulation for different values of the threshold C ranging from 0.5 to 0.9 (see Table 2). Note that S_5 corresponds to the threshold value $C = 0.9$. We consider $p_1 = 0.99, p_w = 0.001, p_c = 0.9$ and four values of $p_2 = 0.3, 0.4, 0.5, 0.6$. From Table 2, we see that the success probability increases as the threshold value C decreases and p_2 increases. Similarly, the number of search decreases with both C and p_2 .

7. Discussion

One prime object of this paper is to show the effect of the neighboring nodes in detection of an event. In this section, we discuss the role of the neighboring nodes, some other related issues and make remarks.

7.1 Role of the neighboring nodes

Since $\ln L_N = a + b(cz_N + t_N - dk(N))$, where a, b, c and d are as defined in Section 4.1, c denotes the weight of the central node compare to the neighboring nodes in the corresponding likelihood. Note that, since $P_1 > P_2$, we have $c > 1$ and, if c is close to 1, then the six neighboring nodes are as important as the event node. So, as the value of c increases, the importance of the neighboring nodes decreases. Also, d gives some idea about the role of the number of adjacent nodes, i.e., $k(N)$. Recall that P_1 and P_2 are the probabilities of responding (i.e., reporting the node N as the event hexagon) by the sensors S_N and $S_{N'}$, respectively, when N is the event hexagon and N' is a neighboring node of N . So, we numerically calculate the quantities P_1, P_2, c and d for some values of the parameters (see Table 3).

From the theoretical results in Section 4.1 we see that, P_1 and c increase as p_1 increases, while P_2 and d do not depend on p_1 . On the other hand, while P_2 increases with p_2 , c and d decreases and P_1 is independent of p_2 . Therefore, the importance of the neighboring nodes decreases with p_1 and increases with p_2 , as expected and observed in Table 3.

7.2 Estimation of the parameters

In practice, the parameters p_1, p_2, p_w and p_c may be unknown. We can, however estimate the parameters by some experimentation.

Note that, under \mathcal{M}_0, Z_N follows $\text{Ber}(p_w)$ for all $N \in R$. Hence, p_w is the expected value of Z_N given \mathcal{M}_0 . So we perform the experiment by keeping the ROI normal. The proportion of Z_N 's having value 1 gives an estimate of p_w . Repeat this experiment several times so that the average of the proportions over the repeated experiments can be taken as an estimate of p_w .

Note that, p_1 is the expected value of Y_N under \mathcal{M}_N . So, we perform the experiment by keeping an event in some node N of the ROI. The proportion of Y_N 's having value 1 gives an estimate of p_1 . Repeat this experiment for several times so that the average of the proportions over the repeated experiments can be taken as an estimate of p_1 . Similar experiments will give estimates of p_2 and p_c as well.

7.3 Incorporation of heterogeneity and uncertainty in parameters

Let $\theta = (p_1, p_2, p_c, p_w)$ denote the set of parameters, which has been assumed to be the same for all the nodes. While, in practice there is no reason why the parameters should be same for all the nodes, it is also not clear how these would be different across N . This unexplained heterogeneity can be incorporated by assuming the θ 's, for different N , to be independent realizations from a common distribution.

Let $\theta_N = (p_{1N}, p_{2N}, p_{cN}, p_{wN})$ denote the set of parameters for node N . We assume that $\theta_N, N \in R$, are i.i.d. from some distribution, say, $g(\theta)$. Also assume that, given $\theta_N, N \in R$, Z_N 's are independent. Note that $g(\theta)$ denotes the joint distribution of the four parameters. For simplicity, we may assume them to be independent so that $g(\theta)$ can be written as $g(\theta) = g_1(p_1)g_2(p_2)g_c(p_c)g_w(p_w)$. In this situation, the likelihood for the model \mathcal{M}_0 is

$$\prod_{N \in R} \int p_{wN}^{z_N} (1 - p_{wN})^{(1-z_N)} g_w(p_{wN}) dp_{wN},$$

where the integration is over the range of p_{wN} . Similarly, the likelihood for the model \mathcal{M}_N can be written as

$$\prod_{N' \in R} \int L_N^{(N')}(\theta_N) g(\theta_N) d\theta_N,$$

where the integral is over the four-dimensional space given by the range of θ_N , and $L_N^{(N')}(\theta_N)$ is the contribution of the N' th node to the likelihood L_N , given the value θ_N , as described in Section 4.1.

Similar technique can also be used to incorporate parameter uncertainty. Even though the parameters can be assumed to be same for all the nodes, there may be reasonable uncertainty about the constancy of the parameter values. As in the Bayesian paradigm, the set of parameters may be assumed to be a realization from a distribution, say, $g(\theta)$. Then, the likelihoods for the model \mathcal{M}_0 and \mathcal{M}_N are

$$\int \prod_{N \in R} p_w^{z_N} (1 - p_w)^{(1-z_N)} g_w(p_w) dp_w \quad \text{and} \quad \int \prod_{N' \in R} L_N^{(N')}(\theta) g(\theta) d\theta \quad \text{respectively.}$$

The choice of $g(\theta)$ may be a difficult one. However, sometimes there may be specific information available regarding the distribution of θ , which can be incorporated in the model.

7.4 When more sensors can detect the event square

We may consider the situation when sensing radii are larger and more sensors can detect the event hexagon but with different probabilities. With respect to a particular node, classify the remaining nodes with respect to the probability of detecting the event at that node, which may as well depend on the distance from the particular node. Suppose that the sensors in the i -th class detect the event hexagon with probability $p_i, i = 1, 2, 3, \dots$. The theoretical analysis is similar to that of Section 4, but having more probability terms.

7.5 Concluding Remarks

In this paper, we consider the problem of fault detection in wireless sensor network (WSN). We discuss how to address both the noise-related measurement er-

rors (p_1 and p_2) and sensor fault (p_c and p_w) simultaneously in fault detection, where the ROI is partitioned into regular hexagons with the event occurring at only one hexagon. We propose fault detection schemes that explicitly introduce the error probabilities into the optimal event detection process. We develop the schemes under the consideration of model selection technique, multiple model selection technique and Bayesian model averaging method. The different error probabilities are calculated by means of simulation. Note that the same analysis can be carried out when ROI is partitioned into squares and sensors are placed at the centers.

Nandi et al. [16] consider similar problem in wireless sensor network (WSN), in which the event can take place at the center of one particular square (or hexagon) of the grid covering the ROI. In our paper, we allow the event square to be any one in the grid. Our approach can also be used for the problem of [16] with only two models to be considered for selection. In [16], the authors develop the scheme under the consideration of Neyman-Pearson hypothesis test, where the null and alternative hypotheses correspond to the two models. In model selection approach, we select the model with higher likelihood. In classical Neyman-Pearson hypothesis test, a model is selected if its likelihood is greater than some constant times the likelihood of the other. This constant is fixed before the test depending on the size of the test. In model selection approach, the constant is 1, leaving no choice for the size of the test. On the other hand, we cannot apply the classical Neyman-Pearson test with more than two models to be considered for selection.

The principle of hypothesis testing places a large confidence in the null hypothesis and does not reject it unless there is strong evidence against it. This safeguard of null hypothesis cannot be ensured in the model selection approach of Section 4.1. However, the multiple model selection approach of Section 4.2 provides some safeguard in this regard.

This principle of model selection can be extended to the situation when there are more than one event hexagon and the objective is to detect the event hexagons. We may also assume that the sensors can detect different types of events. That is, response of sensors may not be only binary; sensors can measure distance, direction, speed, humidity, wind speed, soil makeup, temperature, etc., and send the measurement of continuous type variables to the base station. One needs a different formulation of the problem in such case which will be taken up in future.
